

- The following image demonstrates all 3 previously discussed principals:

- **The horizontal lines represent an orbital**
- **Each half-arrow represents an electron**

		Aufbau principle: Electrons fill orbitals of progressively higher energy	Pauli exclusion principle: An orbital contains no more than two electrons	Hund's rule: Degenerate orbitals are partially filled before any orbital is completely filled

	Ne	Na	Mg	Al	Si

- The most outer shell which houses electrons is known as the **Valence Shell**

- It is the outer perimeter of the atom
 - For example, oxygen has 8 electrons and would look like this graphically:
 - Therefore, the electron configuration would be noted as **$1s^2 2s^2 2p^4$**

- **The number of electrons in an element increases by 1 as you move from left to right across a period**

- E.g. carbon has 6, nitrogen has 7 and oxygen has 8
 - **Elements from the same group have the same number of valence electrons**
 - E.g. hydrogen, lithium and sodium all have 1 valence electron
 - **This means that they are likely to exhibit similar degrees of chemical reactivity**

Shell 2	2s	↑↓
Shell 1	1s	↑↓

- Atoms **can gain or lose electrons**, this is a process known as **ionisation**

- The addition of an electron turns the atom negative, into an **anion**
- The removal of an electron turns the atom positive, into a **cation**
- **Ionisation energy** determines how easily an atom will lose an electron
 - This becomes progressively **more difficult as you move across the periodic table**
 - Therefore, **atoms on the left side of the table are significantly more reactive** than the right side
 - This process has become the basis of some analytical techniques such as **mass spectroscopy**
